

CORRESPONDENCE

(To the Editors of the Journal of the Institute of Actuaries)

(J.I.A. Vol. LXXIII, p. 423)

DEAR SIRS,

In his *Note on the Gompertz Table*, Mr Fraser regrets not being able to explain in a brief and simple way why the 'abacus' could be used to calculate the coefficients A_0, A_1, A_2, \dots .

The following explanation I found when I put to myself the question: 'How did Mr Fraser get the inspiration to try and "alternate" the "abacus"?'.

I began by systematically writing down l_x and its first derivatives, so that the terms with the same powers of μ_x came into the same column.

	1	2	3
$l_x = l_x$			
$Dl_x =$	$-l_x\mu_x$		
$D^2l_x =$	$-l_x\mu_x(\lambda c)$	$+l_x\mu_x^2$	
$D^3l_x =$	$-l_x\mu_x(\lambda c)^2$	$+3l_x\mu_x^2(\lambda c)$	$-l_x\mu_x^3$
$D^4l_x =$

For one familiar with the 'abacus' the resemblance is not difficult to spot. To explain it we must bear in mind that:

- (1) Applying the operator D to l_x is the same as multiplying l_x by $-\mu_x$; in the scheme above this means that the term is transferred to the next row and the next column.
- (2) Applying the operator D to μ_x is the same as multiplying μ_x by λc ; this means that the term is transferred to the next row but stays in the same column.
- (3) The number of the column is the same as the power of μ_x ; applying the operator D to the power of μ_x gives this number as an extra factor.

Let us call the term in the m th row and the n th column $T_{m, n}$. It is clear that

$$T_{m+1, n} = -\mu_x T_{m, n-1} + n\lambda c T_{m, n}.$$

If we put

$$T_{m, n} = C_{m, n} l_x \mu_x^n (\lambda c)^{m-1},$$

we find that

$$C_{m+1, n} = -C_{m, n-1} + nC_{m, n},$$

which is the law of formation of the 'alternating abacus'.

Yours faithfully,

E. STELLER

July 1948

(*To the Editors of the Journal of the Institute of Actuaries*)

DEAR SIRS,

Mortality of Indian assured lives

For some years the Prudential Assurance Company, Limited of London and the National Insurance Company, Limited of Calcutta have been associated in a combined investigation into the mortality of Indian assured lives and an appreciable volume of data has now been collected.

We feel that the results of the investigation may be of value to, and should be made available for the use of, other actuaries. Accordingly, we have prepared, and enclose for publication in the *Journal*, tables summarizing the mortality experience for the years 1934-45. The tables show the exposed to risk and actual deaths, the expected deaths on various appropriate standard tables, and the ratio of actual to expected deaths in quinary age-groups. The period of twelve years has been subdivided into three periods of four years each to show the secular trend of the mortality. The effect of selection is shown by the separation of the durations 0 to 4.

For the guidance of actuaries who may wish to make use of the data, a few notes on the methods of construction employed are appended.

- (1) The data relate to first-class Indian male assured lives. (European lives have been excluded.)
- (2) Joint life assurances, pure endowments with return of premiums, children's deferred assurances prior to vesting, and all policies converted to paid-up assurances have been excluded.
- (3) The investigation is based on policies.
- (4) The duration is the curtate duration from entry.
- (5) Deaths which were directly attributable to war causes have been excluded from the 'actual deaths'.
- (6) The 'Census' method, used for the Continuous Mortality Investigation, was adopted in compiling the exposed to risk and actual deaths. The ages at each 31 December for the in-force, and the ages at the date of death, were calculated by rules which produced on the average the nearest ages at those dates. The exposed to risk, which may be assumed to relate to the year of age $x - \frac{1}{2}$ to $x + \frac{1}{2}$, was derived as follows: if $P(x, T)$ = number of policies in force at nearest age x at 31 December of the calendar year T , and $\theta(x, T)$ = actual deaths at nearest age x in the calendar year T , then exposed to risk of death in the year of age $x - \frac{1}{2}$ to $x + \frac{1}{2}$ in respect of the calendar year T is

$$E(x - \frac{1}{2}, T) = \frac{1}{2} \{P(x, T-1) + P(x, T) + \theta(x, T)\}.$$

The ages shown in the table are the ages at the beginning of the year of exposure, i.e. $x - \frac{1}{2}$ above.

Correspondence

We wish to record our indebtedness to Mr H. L. Humphreys, A.I.A., late actuary of the National Insurance Company, Limited, and to members of the staffs of both Companies for their collaboration in the preparation of the data.

Yours faithfully,

W. F. GARDNER
